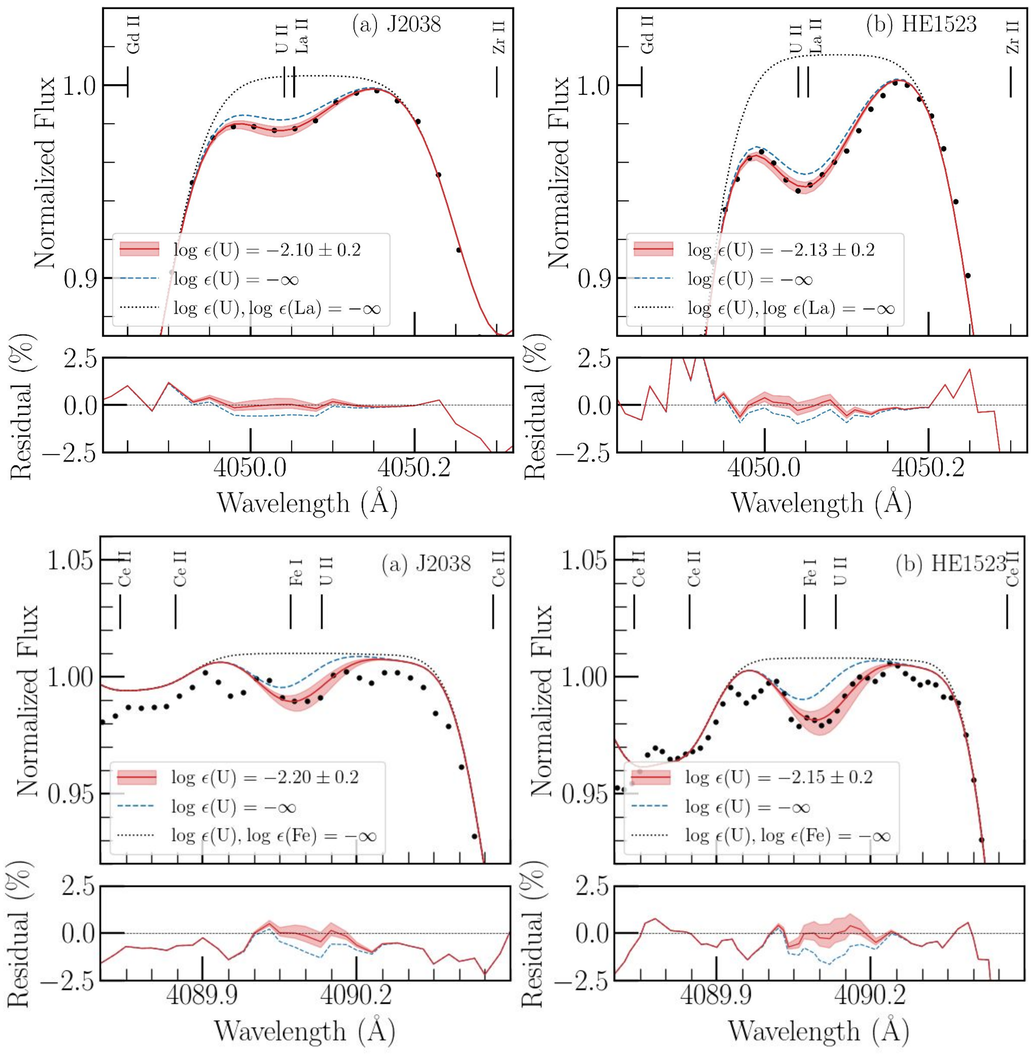
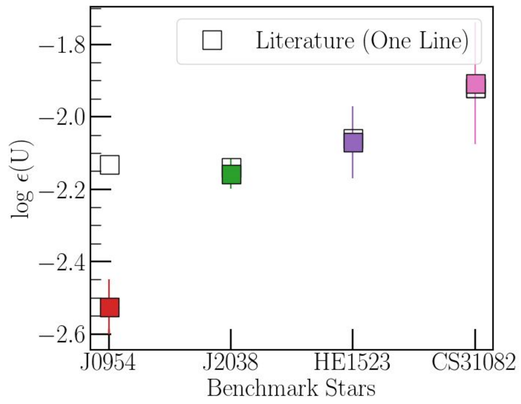
Uranium: An important *r*-process element, but difficult to detect!

- Uranium (U) is the heaviest stable element produced in the universe and belongs to the actinide group of elements.
- It's abundance is sensitive to the physical conditions of the enrichment event.
- Additionally, U is radioactive offering the opportunity to estimate the age of the enrichment event.
- However, of the ~100 *r*-process enhanced stars discovered so far, U has been detected in only ~6.
- The canonical absorption line used is heavily blended.

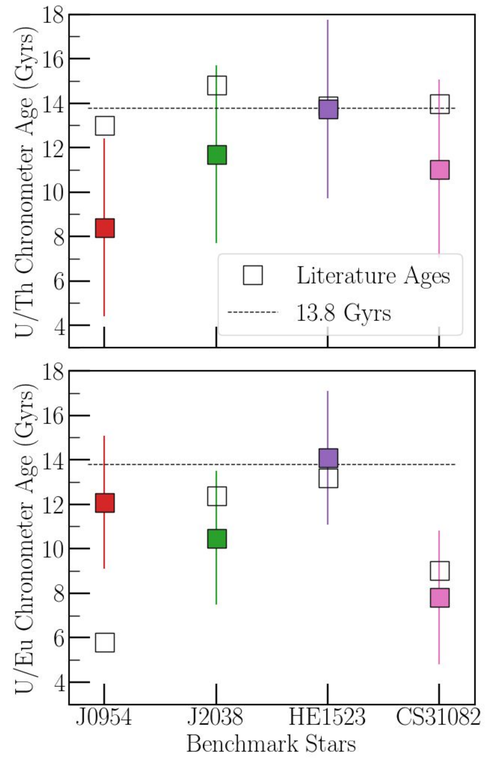
We derive uranium abundance for 4 benchmark *r*-process enhanced stars using absorption lines at 4050.04 Å (top) and 4090.31 Å (bottom).



Sample Stars: J0954, J2038, HE1523, CS31082
Instrument: Keck/HIRES, MIKE/Magellan, UVES/VLT, UVES/VLT
Resolving Power: > 60,000
Signal-to-Noise Ratio: > 150
Radiative transfer code: MOOG (Sneden) (https://github.com/alexji/moog17scat)
Model Atmosphere: 1D ATLAS9 (Castelli and Kurucz)
Linelist: linemake (https://github.com/vmplacco/linemake)
Spectroscopic analysis: Spectroscopy Made Harder (https://github.com/eholmbeck/smhr-rpa)



Mean U abundance using 3859, 4050 and 4090 Å absorption lines comparable to literature abundances from 3859 Å line.



Age estimates of the stars using radioactivity of U and Th. First age-estimates using multiple U lines!
